ISUOG Practice Guidelines: performance of fetal magnetic resonance imaging

Clinical Standards Committee

The International Society of Ultrasound in Obstetrics and Gynecology (ISUOG) is a scientific organization that encourages sound clinical practice, and high-quality teaching and research related to diagnostic imaging in women’s healthcare. The ISUOG Clinical Standards Committee (CSC) has a remit to develop Practice Guidelines and Consensus Statements as educational recommendations that provide healthcare practitioners with a consensus-based approach, from experts, for diagnostic imaging. They are intended to reflect what is considered by ISUOG to be the best practice at the time at which they are issued. Although ISUOG has made every effort to ensure that Guidelines are accurate when issued, neither the Society nor any of its employees or members accepts any liability for the consequences of any inaccurate or misleading data, opinions or statements issued by the CSC. The ISUOG CSC documents are not intended to establish a legal standard of care because interpretation of the evidence that underpins the Guidelines may be influenced by individual circumstances, local protocol and available resources. Approved Guidelines can be distributed freely with the permission of ISUOG (info@isuog.org).

These guidelines are based on consensus reached between participants following a survey of current practices, conducted by ISUOG in 2014 (Appendix S1).

INTRODUCTION

Fetal magnetic resonance imaging (MRI) is an important diagnostic imaging adjunct to ultrasonography1, particularly for the assessment of fetal brain development2. A survey conducted by ISUOG in 2014 (Appendix S1), in which 60 international perinatal centers participated, showed that fetal MRI is being performed in one or more centers in at least 27 countries worldwide. However, the quality of imaging, sequences used and operator experience appear to differ widely between centers3.

The impact of such differences should be reduced by development of guidelines to define better the role of fetal MRI in relation to prenatal diagnostic ultrasound. The aim of this document is to provide information on state-of-the-art fetal MRI for those performing the examination, as well as for clinicians interpreting the results.

What is the purpose of fetal MRI?

The purpose of fetal MRI is to complement an expert ultrasound examination4,5, either by confirmation of the ultrasound findings or through the acquisition of additional information6. MRI is not currently used as a primary screening tool in prenatal care, although standardized and complete assessment of the fetal anatomy is probably feasible. Figure 1 presents the survey participants’ opinions regarding indications for which MRI can provide useful information.

Is fetal MRI a safe procedure?

MRI is not associated with known adverse fetal effects at any point in pregnancy, when performed without administration of contrast media7. There are no reported adverse effects of MRI performed at 1.5 Tesla (1.5 T)8. However, there have been no human studies of possible adverse effects at higher field strength, such as 3.0 T7,9,10, although recent data show that it may be safe in a porcine model11.

Under which circumstances should fetal MRI be performed?

There is general consensus that fetal MRI is indicated following an expert ultrasound examination in which the diagnostic information about an abnormality is incomplete. Under these circumstances, MRI may provide important information that may confirm or complement the ultrasound findings and alter or modify patient management.

Presently, factors influencing the decision to perform fetal MRI include, but are not limited to: experience/equipment of the ultrasound and MRI facilities, accessibility to MRI, maternal conditions, gestational age, safety concerns, legal consideration regarding termination of pregnancy (TOP) and parental wishes after appropriate counseling4,10,12,13.

The ISUOG survey addressed the necessity of MRI for selected indications and used a 7-point rating scale to weight the responses from 0 (not at all indicated) to 7 (definitely indicated) (Figure 1). The variety of responses is likely to reflect the divergence seen between various specialties and the spectrum of pathologies seen at each
Figure 1 Results of ISUOG survey on indications for fetal magnetic resonance imaging (MRI), rated on a scale from 0 (fetal MRI not at all indicated) to 7 (definitely an indication for fetal MRI). *History of abnormality in previous pregnancy or in family member, with normal ultrasound (US) findings in current pregnancy. TTTS, twin–twin transfusion syndrome; VM, ventriculomegaly.

Table 1 The multidisciplinary team: proposed participants and their role in performing fetal magnetic resonance imaging (MRI)

center. The opinions may also reflect different levels of experience when performing fetal ultrasound and MRI.

In general, performance of an ultrasound examination following only the minimum recommendations for second-trimester ultrasound/basic brain examination, as proposed by ISUOG, is insufficient prior to requesting MRI. Additional views, such as orthogonal views, higher frequency probes and/or transvaginal imaging are required to detail the specific abnormality.

The practice of TOP and associated medicolegal implications may influence the use of fetal MRI at local institutions. In countries in which the decision about TOP has to be made before 24 weeks, the performance of MRI prior to this time may help an individual couple decide on the future of their pregnancy; however, in general, MRI is better reserved for later in the second or third trimester. Although available data are still inconclusive, MRI for parental reassurance regarding the absence of associated pathologies in fetuses with apparently isolated conditions may be recommended in fetuses with isolated ventriculomegaly, agenesis of the corpus callosum, absent septum pellucidum and cerebellar or vermian anomalies. In addition, fetal MRI has been found to be helpful in monochorionic twin pregnancies after iatrogenic or natural demise of a cotwin to find pathological changes in the surviving twin.

At what gestational age should fetal MRI be performed?

Fetal MRI performed before 18 weeks does not usually provide information additional to that obtained on ultrasound examination. In some cases, additional information can be obtained before 22 weeks but MRI becomes increasingly helpful thereafter. Specific examples of pathologies that can be evaluated in the third trimester include, but are not limited to, those of cortical development and neck masses that may cause airway compromise. Most organs can be visualized in detail between 26 and 32 weeks of pregnancy, when pathologies related to abnormal development are more
Where should a practitioner train for fetal MRI?

Although at present we are unaware of the existence of a recognized fetal MRI specialization, individuals who perform fetal MRI should have undergone specialized training in collaboration with a teaching center, enabling them to perform a state-of-the-art fetal MRI examination after a sufficient amount of cases (GOOD PRACTICE POINT; i.e. recommended best practice based on the clinical experience of the guideline development group).

A teaching center is defined as an institution that is able to teach students, physicians and radiographers/technologists skillful performance of fetal MRI. In order to qualify as a teaching center certain requirements should be fulfilled, which include:

1. multidisciplinary specialists working in the field, including, but not limited to, fetomaternal specialists, radiologists and obstetricians;
2. institutional experience, with at least 500 fetal MRIs and at least two examinations performed per week;
3. publication of scientific papers or reference material in this field (Figure 2).

RECOMMENDATIONS

Performance of fetal MRI according to standardized criteria (Table 2) will improve the management of pregnancies complicated by a fetal malformation or acquired condition (GOOD PRACTICE POINT).

How should fetal MRI be performed?

Field strength

At present, 1.5 T is the most commonly used field strength, providing acceptable resolution even as early as 18 weeks. 3 T has the potential to provide images with higher resolution and better signal-to-noise ratio than does 1.5 T, while maintaining a comparable or lower energy deposition. Nonetheless, higher field strength is currently not recommended for in-vivo fetal imaging.

Course of examination

1. Exclude contraindications for MRI.

Figure 3 Coronal, axial and sagittal (left to right) T2-weighted fast (turbo) spin-echo sequences (with long echo time) of normal fetal brain at 21 + 0 (a), 28 + 1 (b) and 31 + 1 (c) weeks.

Figure 4 Axial T2-weighted fast (turbo) spin-echo sequences in a normal 39 + 4-week fetus showing how a shorter echo time (TE) gives greater detail of the fetal body: (a) TE = 80 ms; (b) TE = 140 ms.
2. Obtain informed consent from the pregnant woman.
3. Note gestational age, ideally as assessed by first-trimester ultrasound\textsuperscript{23}, and pertinent prior clinical assessment and ultrasound findings.
4. Consider using sedation to reduce fetal movements and/or artifacts, and in anxious or claustrophobic patients.
5. Place the patient on the table in a comfortable position\textsuperscript{24}.
6. In some cases, and according to the safety regulations at the particular institution, consider accommodation of an accompanying person in the examination room\textsuperscript{25}.
7. Acquire localizer sequences.
8. Ensure correct coil placement, with first organ of interest in the center of the coil; plan for next sequences.
9. Assess the primary organ of interest.
10. When indicated, proceed to perform a complete examination of the whole fetus and the extrafetal structures (including umbilical cord, placenta and maternal cervix).

ISUOG Guidelines

Figure 6 Sagittal T2-weighted magnetic resonance image of a normal 21 + 5-week fetus, showing the profile with intact palate.

11. Inform referring physician expeditiously if a condition becomes apparent that needs rapid intervention, such as suspected placental abruption or hypoxic ischemic fetal brain injury.

Choice of sequences

1. T2-weighted contrast is the mainstay of fetal MRI and is usually achieved using T2-weighted fast (turbo) spin-echo (SE) or steady-state free-precession (SSFP) sequences. Fast (turbo) SE sequences with long echo time (TE) should be used in imaging of the fetal brain (Figure 3). A shorter TE gives more contrast in the fetal body (Figure 4). SSFP sequences provide T2 information in moving fetuses and allow, for instance, the differentiation of vessels from solid tissue.

2. T1-weighted contrast is acquired by the use of two-dimensional gradient echo (GRE) sequences at 1.5 T. An average duration of 15 s permits performance during a maternal breath-hold, which facilitates the acquisition of images that are free from movement artifacts. T1-weighted contrast identifies methemoglobin in subacute hemorrhage, calcification, glands and meconium (Figure 5a,b).

3. Single-shot high-resolution (SSH) GRE echoplanar (EP) sequences are used to visualize bony structures, calcification and the breakdown products of blood, such as deoxyhemoglobin, which suggests a recent bleed, or hemosiderin, which represents an older hemorrhage (Figure 5c–e).

4. Optional sequences include: diffusion-weighted imaging, diffusion tensor imaging, dynamic SSFP sequences and SSH magnetic resonance cholangiopancreatography sequences, which supply three-dimensional-like images (Figure 5f,g).

In all cases, the field-of-view should be adjusted to the region of interest. A slice thickness of 3–5 mm with a 10–15% intersection gap will be appropriate in most cases. The examination should include at least T2 information in three orthogonal planes of the fetal brain and body, and T1- and GRE-EP sequences in one or two planes, preferably frontal and sagittal.

This ‘minimum’ protocol should be executable in less than 30 min, even allowing for fetal movement and sequence repetition. Only examinations that are performed following this protocol should be regarded as ‘state of the art’ (GOOD PRACTICE POINT).

Standardized planes for fetal brain examination

1. Sagittal sections through the head, including a mid-sagittal plane depicting the corpus callosum, aqueduct and pituitary.

2. Coronal sections parallel to the brainstem with symmetrical visualization of the inner ear structures.

3. Axial sections, perpendicular to the sagittal sections, parallel to the course of the corpus callosum (or skull base in the case of absence of the corpus callosum), with lateral symmetry adjusted according to the coronal sections.

Figure 7 Magnetic resonance imaging (MRI) of normal fetal chest (a,b) and abdomen (c,d). (a) Axial T2-weighted MRI in a 34+2-week fetus, showing normally shaped thorax and lungs with age-matched regular signals; (b) coronal image at 35+3 weeks, showing additionally parts of liver, kidneys and adrenal gland on right side. (c) Coronal T2-weighted MRI in a 32+2-week fetus, displaying fluid-filled stomach and bowel loops; (d) sagittal steady-state free-precession image in a 35+6-week fetus, showing in addition the fluid-filled urinary bladder. Note hyperintensity of the heart in (d), in contrast to T2-weighted image (c).

Standardized planes for fetal body examination

These are more difficult to achieve, as the fetus is usually in a position that will not allow strictly orthogonal placement of slices.

1. Sagittal sections can be achieved by placing the middle slice through the thoracic spine and the umbilical cord insertion.

2. Coronal sections have to be adjusted to the course of the spine (parallel to the thoracic spine and the frontal body wall at the level of the abdomen).

3. Axial slices should be perpendicular to the long axis of the spine at the level of the region of interest. To perform lung volumetry, for instance, the axial sections should be perpendicular to the thoracic spine.
Although usually measurements will already have been made with ultrasound, measuring certain structures at the MRI examination may be of benefit in particular cases. When measuring fluid-containing structures, it is important to remember that MRI measurements are usually around 10% greater than the corresponding ultrasound measurements. In lung volumetry, normal gestational-age related MRI measurements correlate with fetal body volume and are considered predictive of outcome in cases of lung pathology.

Storage of magnetic resonance images

The whole examination should be stored according to local practice, preferably in electronic format. CDs of the examinations can be produced for the patient to enable second-opinion assessment (GOOD PRACTICE POINT).

Reporting

Two types of examination should be distinguished clearly and identified in the report:

1. A targeted examination, which looks only for a certain category of fetal anomaly. The aim is to target a specific organ or address a particular question and not to evaluate the entire fetus.
2. A detailed examination, which includes a standardized evaluation of the whole fetal anatomy in a similar way to that described by the ISUOG guidelines for second-trimester ultrasound (or other locally used guidelines) (Table 3). This examination may include structures less amenable to MRI than to ultrasound examination, for example cardiac structures. Extrafetal structures, such as the umbilical cord, placenta and cervix, and the amniotic fluid (amount and signal intensity), should be described when indicated clinically. Structures not sought routinely in these examinations need to be indicated clearly in the report.

Standardized reports should follow the suggested structure outlined in Table 3 (GOOD PRACTICE POINT).

Figure 8 T2-weighted sagittal (a) and axial (b) magnetic resonance images in a normal 31 + 1-week female fetus, showing external genitalia. Steady-state free-precession sagittal (c) and axial (d) images in a 35 + 1-week male fetus with descended testes and hydrocele, in this case as a consequence of a liver tumor.
Figure 9 T2-weighted sagittal magnetic resonance image through maternal abdomen, showing normal cervix at 33 weeks’ gestation.

As MRI is usually not a first-line examination, but a complementary examination following an ultrasound examination performed in the second trimester\textsuperscript{31}, the emphasis of the examination and report should be on structures that are more difficult to assess with ultrasound. A detailed anatomical assessment may be performed on demand.
